## ABSTRACT

Consider a static scene and fixed center of projection, about which a camera is free to zoom, pan, tilt, and rotate about its optical axis. With an ideal camera, the resulting images are in the same orbit of the projective group-action, and each pixel of each image provides a measurement of a ray of light passing through a common point in space. Unfortunately, most modern cameras have a built in automatic gain control (AGC), automatic shutter, or auto-iris, which, in many cases cannot be turned off. Many modern digitizers to which cameras are connected have their own AGC which also cannot be disabled. With AGC, the characteristic response function of the camera varies, making it impossible to accurately describe one image as a projective coordinate transformed version of another. This paper proposes not only a solution to this problem, but a means of turning AGC into an asset, so that even in cases where AGC could be disabled, pencigraphers of the future will be turning AGC on.

## 1. INTRODUCTION

Suppose we take two pictures, using the same settings (in manual exposure mode), of the same scene, from a fixed common location (e.g. where the camera is free to zoom, pan, tilt, and rotate about its optical axis between taking the two pictures). Both of the pictures capture the same pencil of light[1], but each one projects this information differently onto the film or image sensor. Neglecting that which falls beyond the borders of the pictures, the images are in the same orbit of the projective group of coordinate transformations. The use of projective (homographic) coordinate transformations to automatically (without use of explicit features) combine multiple pictures of the same scene into a single picture of greater resolution or spatial extent, was first described in 1993[1]. These coordinate transformations were shown to capture the essence of a camera at a fixed center of projection (COP) in a static scene.

Note that the projective group of coordinate transformations is not Abelian and there is thus some uncertainty in the estimation of the parameters associated with this group of coordinate transformations[2]. However, we may first estimate parameters of Abelian subgroups (for example, the pan/tilt parameters, perhaps approximating them as a 2-D translation so that Fourier methods[3] may be used). Estimation of zoom (scale) together with pan and tilt, would incorporate non-commutative paramters (zoom and translation don't commute), but could still be done using the *multiresolution Fourier transform*[4][5], at least as a first step, followed by an iterative paramter estimation procedure over all paramters. An iterative approach to the estimation of the parameters of a projective (homographic) coordinate transformation between images was suggested in[1], and later in [6] and [7].

Lie algebra is the algebra of symmetry, and pertains to the behaviour of a group in the neighbourhood of its identity. With typical video sequences, coordinate transformations relating adjacent frames of the sequence are very close to the identity. Thus we may use the Lie algebra of the group when considering adjacent frames of the sequence, and then use the group itself when combining these frames together. Thus, for example, to find the coordinate transformation, $p_{09}$, between $F_0(x,y)$, Frame 0 and $F_9(x,y)$, Frame 9, we might use the Lie algebra to estimate $p_{01}$ (the coordinate transformation between Frame 10 and 11) and then estimate $p_{12}$ between frames $F_1$ and $F_2$, and so on, each one being found in the neighbourhood of the identity. Then to obtain $p_{09}$, we use the **true law of composition** of the group: $p_{09} = p_{01} \circ p_{12} \circ \ldots \circ p_{89}$.

### 1.1. IDEAL SPOTMETER

An ideal spotmeter is a perfectly directional lightmeter which measures the quantity of light, $q$, arriving from the direction in which it is pointed. The direction in which it is pointed may be specified in terms of its azimuth, $\theta$, and its elevation, $\phi$.

The 'pencigraph'[2] is a recording of the pencil of light rays passing through a given point in space, and could, in principle, be measured with a dense array of spotmeters aimed toward that point. (Fig 1).

Panoramic photography attempts to record a large portion of the 'nonmetric pencigraph'[3] onto a single piece of film (often by rotating the camera while sliding the film through a slit). The nonmetric pencigraph may also be estimated from a collection of pictures all taken from the same point in space (with differing camera orientations and lens focal lengths).

This work sponsored in part by HP Labs.

[1] We neglect the boundaries of the sensor array and assume that both pictures have sufficient field of view to capture all of the objects of interest.

[2] Terminology in single quotes is that defined by the author here or elsewhere.

[3] By *nonmetric*, I mean that even if we know the exact direction of arrival corresponding to each pixel in the panoramic picture, it does not tell us the actual quantity of light arriving from that direction.

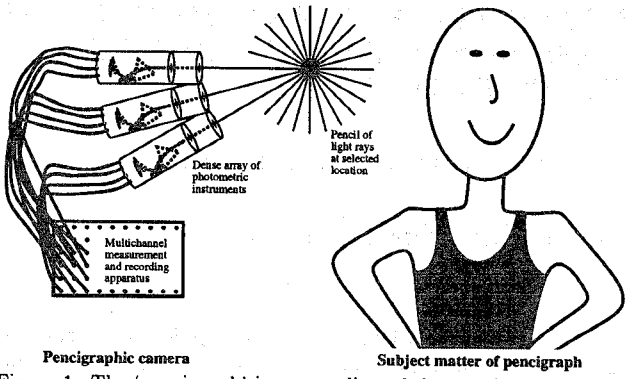

Figure 1: The 'pencigraph' is a recording of the pencil of light rays passing through a given point in space. Such a recording could be approximated by a discrete array of spotmeters, angled toward a common point — the center of projection.

The basic philosophy is that the camera may be regarded as an array of (nonmetric) spotmeters, measuring rays of light passing through the COP. To each pair of pixel indices of the sensor array in a camera, we may associate an azimuth and elevation. Eliminating lens distortion[8] makes the images obey the laws of projective geometry, so that they are (to within image noise and cropping) in the same orbit of the projective group action. (Lens distortion may also be simply absorbed into the mapping between pixel locations and directions of arrival.)

Trying to use a pixel from a camera as a lightmeter raises many interesting and important problems. The output of a typical camera, $f$, is not linear with respect to the incoming quantity of light, $q$. For a digital camera, the output, $f$, is the pixel value, while for film, the output might be the density of the film at the particular location under consideration. I will assume that the output is some unknown but monotonic function of the input. Monotinicity, a weaker constraint than linearity, is what I mean by "nonmetric spotmeter" — our knowledge of the quantity of light received is in terms of the nonmetric quantity $f(q)$, not $q$ itself.

Models for the nonlinearity, $f$, include the classic response curve[9]:

$$f(q) = \alpha + \beta q^{\gamma} \tag{1}$$

or the author's $f = \alpha + exp(1/2 + \arctan(\gamma \log(q) + \beta)/\pi$ curve that attempts to capture the toe and shoulder regions of the response. Methods to estimate the unknown response curve from pictures that differ only in exposure, have also been proposed[10]. These methods are based on computing the joint histogram between differently exposed pictures, and then estimating the function $g(f)$, defined by

$$g(f(q(x,y))) = f(kq(x,y)) \tag{2}$$

where $q(x,y)$ is the quantity of light received in a first exposure, and $kq(x,y)$, the quantity of light received in a second exposure, is $k$ times that of the first exposure. In traditional film cameras, $k$ would most likely be $2^n$, $n \in \mathbb{Z}$, but in electronic cameras, $k$ may vary continuously. Since the response curve, $f$, is assumed to be unknown, we begin with the estimates of the so-called 'range-range'[10] plots, $g(f(q)) = f(kq)$ versus $f(q)$ (so-called because they represent the range of the response curve plotted against the range of the response curve for a different exposure). Examples of the range-range plots for various values of $k$, appear in Fig 2. (These plots completely characterize the response of a specific camera and digitizer — a system designed and built by the author, comprising a miniature camera built into a pair of eyeglasses together with a tiny computer screen, connected to clothing containing a digitizer with Internet connection; further information is available from the Web site listed in the titlepage.)

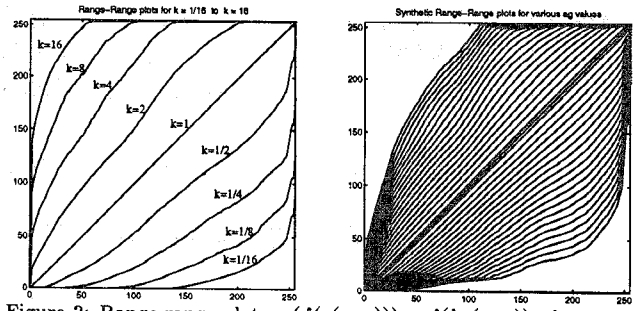

Figure 2: Range-range plots, $g(f(q(x,y))) = f(kq(x,y))$, characterizing the specific camera and digitizer combination used by author. (a) plots estimated from joint histograms of differently exposed pictures of the same scene. (b) family of curves generated by the 'exact' model, for various values of the input parameter.

### 1.2. AGC

If what is desired is a picture of increased spatial extent or spatial resolution, the nonlinearity is not a problem, so long as it is not image dependent. However, most low-cost cameras have a built in automatic gain control (AGC), electronic level control, auto iris, or some other form of automatic exposure[4] which cannot be turned off or disabled. This means that the unknown response function, $f(q)$, is image dependent, and will therefore change over time, as the camera framing changes to include brighter or darker objects.

Although AGC was a good invention for its intended application (serving the interests of most camera users who merely wish to have a properly exposed picture without having to make adjustments to the camera), it has previously thwarted attempts to estimate the projective coordinate transformation between frame pairs. Examples of an image sequence, acquired using a camera with AGC, appear in Fig 3.

The purpose of this paper is to propose a joint estimation of the projective coordinate transformation and the tone-scale change. Each of these two may be regarded as a "motion estimation" problem if we extend the concept of "motion estimation" to include both 'domain motion' (motion in the traditional sense) as well as 'range motion' (Fig 4).

## 2. JOINT ESTIMATION OF BOTH DOMAIN AND RANGE "MOTION"

As in[6], we consider one dimensional "images" for purposes of illustration, with the understanding that the actual operations are performed on 2-D images. The 1-D projective-

[4] I refer to all of these methods of automatic exposure control as AGC, whether or not they are actually implemented using gain.

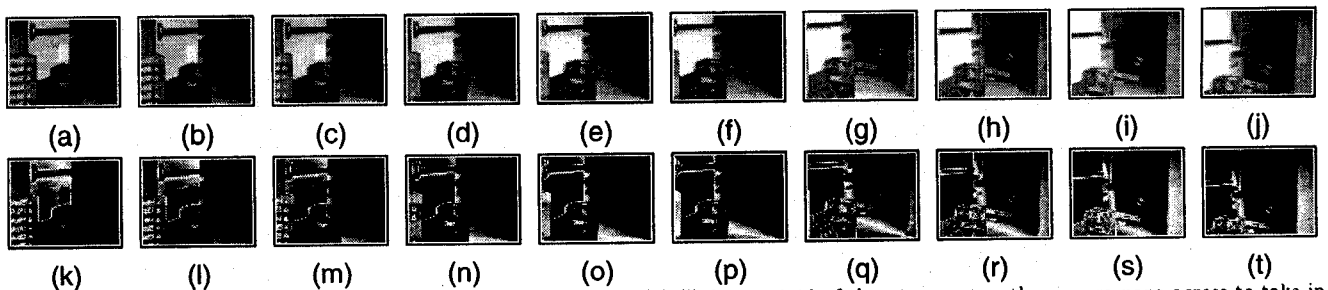

Figure 3: The 'fire-exit' sequence, taken using a camera with AGC. (a)-(j) frames 1-10 of the sequence: as the camera pans across to take in more of the open doorway, the image brightens up showing more of the interior, while, at the same time, clipping highlight detail. Frame 10 (a) shows the writing on the white paper taped to the door very clearly, but the interior is completely black. In frame 13 (d) and beyond, the paper is completely obliterated, but more and more detail of the interior becomes visible, showing that the fire exit is blocked by the clutter inside. (k)-(t) 'certainty' images corresponding to (a)-(j).

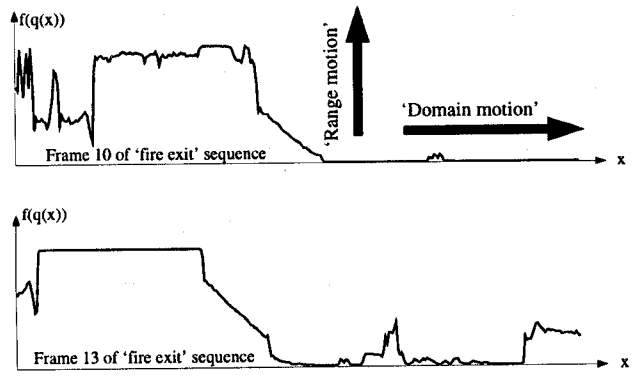

Figure 4: Center rasters of two images from the 'fire exit' sequence. 'Domain motion' is motion in the traditional sense (e.g. motion from left to right, zoom, etc.), while 'Range motion' refers to a tone-scale adjustment (e.g. lightening or darkening of the image). In this case, the camera is panning to the right, so domain motion is to the left. However, when panning to the right, the camera points more and more into the darkness of an open doorway, causing the AGC to adjust the exposure. Thus there is some "upwards" motion of the curve as well as "leftwards" motion. Just as panning the camera across causes information to leave the frame at the left, and new information to enter at the right, the AGC causes information to leave from the top (highlights get clipped) and new information to enter from the bottom (increased shadow detail).

Wyckoff group is defined in terms of the group of projective coordinate transformations, taken together with the one-parameter group of image darkening/lightening operations: $p_{a,b,c,k} \circ f(q(x)) = g(f(q(\frac{ax+b}{cx+1}))) = f(kq(\frac{ax+b}{cx+1}))$ where $g$ characterizes the lightening/darkening operation.

The law of composition is defined as: $(p_{abc}, p_k) \circ (p_{def}, p_l) = (p_{abc} \circ p_{def}, p_k \circ p_l)$ where the first law of composition on the right hand side is the usual one for the projective group, and the second one is that of the one-parameter lightening/darkening subgroup.

Two successive frames of a video sequence are related through a group-action that is near the identity of the group, thus one may think of the Lie algebra of the group as providing the structure locally. As in previous work[6] an approximate model which matches the 'exact' model in the neighbourhood of the identity is used.

For the projective group, the approximate model has the form $q_2(x) = q_1((ax+b)/(cx+1))$.

For the 'Wyckoff group' (which is a one parameter group isomorphic to addition over the reals, or multiplication over the positive reals), the approximate model may be taken from Eq 1, by noting that

$$g(f(q)) = f(kq) = \alpha + \beta(kq)^\gamma = k^\gamma f + 1 - \alpha k^\gamma \qquad (3)$$

This equation suggests that linear regression on the joint histogram between two images would provide an estimate of $\alpha$ and $\gamma$, while leaving $\beta$ unknown, which is consistent the fact that the response curve may only be determined up to a constant scale factor.

From (3) we have that the (generalized) brightness change constraint equation is $g(f(q(x,t))) = f(kq(x,t)) = f(q(x+\Delta x, t+\Delta t)) = k^\gamma f(q(x,t)) + 1 - \alpha k^\gamma$. Combining this equation with the Taylor series representation $F(x+\Delta x, t+\Delta t) = F(x,t) + \Delta x F_x(x,t) + \Delta t F_t(x,t)$, the equation of motion becomes: $F + (ax^2+bx+c)F_x + F_t - k^\gamma F + (1-\alpha k^\gamma) = \epsilon$. Minimizing $\sum \epsilon^2$ yields a linear solution in substituted variables (that are easily related to the variables of the approximate model):

$$\begin{bmatrix} \sum x^4 F_x^2 & \sum x^3 F_x^2 & \sum x^2 F_x^2 & -\sum x^2 F F_x & -\sum x^2 F_x \\ \sum x^3 F_x^2 & \sum x^2 F_x^2 & \sum x F_x^2 & -\sum x F F_x & -\sum x F_x \\ \sum x^2 F_x^2 & \sum x F_x^2 & \sum F_x^2 & -\sum F F_x & -\sum F_x \\ \sum x^2 F F_x & \sum x F F_x & \sum F F_x & -\sum F^2 & -\sum F \\ \sum x^2 F_x & \sum x F_x & \sum F_x & -\sum F & -\sum 1 \end{bmatrix} \begin{bmatrix} (bc-a)c \\ a-bc \\ b \\ k^\gamma \\ 1-\alpha k^\gamma \end{bmatrix} =$$

$$-\left[\sum x^2 F_x(F+F_t), \sum x F_x(F+F_t), \sum F_x(F+F_t), \sum F(F+F_t), \sum (F+F_t)\right]^T$$

where $F(x,t) = f(q(x))$ at time $t$, $F_x(x,t) = (df/dq)(dq(x)/dx)$, at time t, and $F_t(x,t)$ is the frame difference of adjacent frames.

## 3. THE BIG PICTURE

To construct a single floating-point image of increased spatial extent and increased dynamic range, each pixel of the output image is constructed from a weighted sum of the images whose coordinate-transformed bounding boxes fall within that pixel. The weights in the weighted sum are the so-called 'certainty functions'[10], which are found by evaluating the derivative of the corresponding 'effective response function' at the pixel value in question. While the response function, $f(q)$, is fixed for a given camera, the 'effective response function', $f(k_i(q))$ depends on the exposure, $k_i$, associated with frame, $i$, in the image sequence. By evaluating $f_q(k_i(q_i(x,y)))$, we arrive at the so-called 'certainty images' (Fig 3). Lighter areas of the 'certainty images' indicate moderate values of exposure (mid-tones in the corresponding images), while darker values of the certainty images designate exposure extrema — exposure in the *toe* or *shoulder* regions of the response curve where it is difficut to discern subtle differences in expsoure.

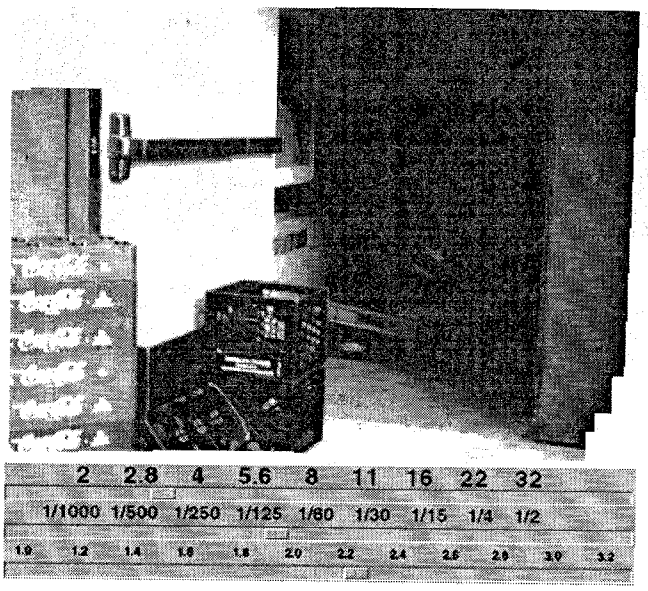

Figure 5: Floating point pencigraphic image constructed from the fire-exit sequence. The dynamic range of the image is far greater than that of a computer screen or printed page. The pencigraphic information may be interactively viewed on the computer screen, however, not only as an environment map (with pan, tilt, and zoom), but also with control of 'exposure' and contrast. With a 'virtual camera' we may move around in the pencigraph, both spatially and tonally.

The pencigraphic estimate may be explored interactively on a computer system (Fig 5), but the simultaneous wide dynamic range and ability to discern subtle differences in greyscale are lost once the image is reduced to a tangible form (e.g. a hardcopy printout).

In order to print a picture of such dynamic range it may be preferable to relax the monotonicity constraint, and perform some local tone-scale adjustments (Fig 6). Even if the end goal is a picture of limited dynamic range (as in Fig 5), perhaps where the artist wishes to deliberately wash out highlights and mute down shadows for expressive purposes, the author's philosopy is that one should attempt to capture as much information about the scene as possible, produce a pencigraphic estimate, and then "put expression" into that estimate (by throwing away information in a controlled fashion) to produce a final picture.

## 4. SUMMARY

The procedure for self-calibrating a camera (to within a constant scale factor) has been exploited for capturing pencigraphic measurements, in particular, treating the camera as an array of photometric measuring instruments. This has been acomplished by proposing and implementing a global motion estimation algorithm which considers jointly global "motion" in the domain and range of the functions undergoing "motion". Dynamic range has been extended by combining differently exposed images where the AGC, rather than thwarting motion estimation algorithms as is generally otherwise the case, actually provides both more information from the scene and information about the camera's unknown response function.

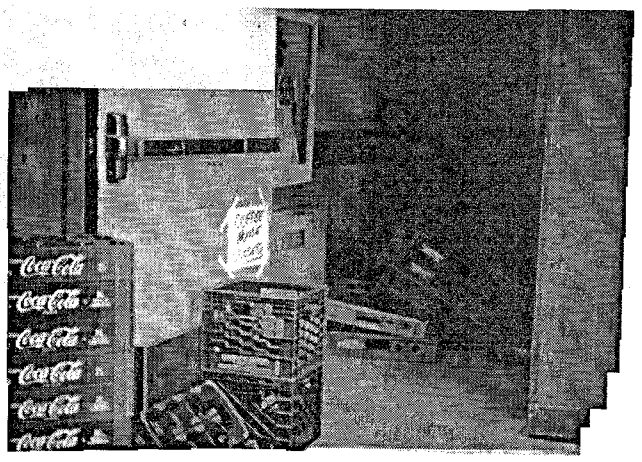

Figure 6: Fixed-point image made by tone-scale adjustments that are only locally monotonic, followed by quantization to 256 greylevels. Note that we can see clearly both the small piece of white paper on the door (and even read what it says — "COFFEE HOUSE CLOSED"), as well as the details of the dark interior.

## 5. ACKNOWLEDGEMENT

Thanks to Rosalind Picard, Charles Wyckoff, Shawn Becker, and Berthold Horn for many interesting discussions.
